## 1 Introduction

Let  $E$  be an elliptic curve over the rational numbers. We can think of  $E$  as the set of rational solutions  $(x, y)$  to a two-variable cubic equation in the form:

$$E : y^2 = x^3 + Ax + B \quad (1.1)$$

for some integers  $A$  and  $B$ , along with an extra "point at infinity". An important criterion is that the  $E$  be a smooth curve; this translates to the requirement that the discriminant  $\Delta(E)$  of the curve, given by  $\Delta(E) = -16(4A^3 + 27B^2)$ , is not zero.

One of the natural questions to ask when considering an elliptic curve is "how many rational solutions are there?" It turns out elliptic curves fall in that sweet spot where the answer could be zero, finitely many or infinitely many - and figuring out which is the case is a deeply non-trivial - and as yet still open - problem.

The rational solutions on  $E$  form an abelian group with a well-defined group operation that can be easily computed. By a theorem of Mordell, the group of rational points on an elliptic curve  $E(\mathbb{Q})$  is finitely generated; we can therefore write

$$E(\mathbb{Q}) \approx T \times \mathbb{Z}^r, \quad (1.2)$$

where  $T$  is a finite group (called the torsion subgroup of  $E$ ), and  $r$  is denoted the algebraic rank of  $E$ .

Determining the torsion subgroup of  $E$  is relatively straightforward. By a celebrated theorem of Mazur, rational elliptic curves have torsion subgroups that are (non-canonically) isomorphic to one of precisely fifteen possibilities:  $\mathbb{Z}/n\mathbb{Z}$  for  $n = 1$  through 10 or 12; or  $\mathbb{Z}/2\mathbb{Z} \oplus \mathbb{Z}/2n\mathbb{Z}$  for  $n = 1$  through 4. However, Computing the rank  $r$  - the number of independent rational points on  $E$  - is hard, and no unconditional method to do so currently exists. It is towards this end that the work in this dissertation hopes to contribute.

Perhaps surprisingly, we can translate the algebraic problem of finding the number of rational solutions on  $E$  to an analytic one - at least conjecturally. The method of doing so is via elliptic curve  $L$ -functions; these are complex-analytic entire functions that somehow encode a great deal of information about the elliptic curve they describe. Unfortunately, it takes a few steps to define them:

**Definition 1.1.** Let  $p$  be a prime number.

- Define  $N_p(E)$  to be the number of points on the *reduced curve*  $E$  modulo  $p$ . That is (excepting the cases  $p = 2$  or  $3$ , for which the definition is slightly more complicated), if  $E$  has equation  $y^2 = x^3 + Ax + B$ , then

$$N_p(E) = 1 + \# \{(\bar{x}, \bar{y}) \in \mathbb{F}_p^2 : \bar{y} \equiv \bar{x}^3 + A\bar{x} + B \pmod{p}\}, \quad (1.3)$$

where the 1 accounts for the aforementioned point at infinity on  $E$  not captured by the above equation.

- Let  $a_p(E) = p + 1 - N_p(E)$ .

Hasse's Theorem states that  $a_p(E)$  is always less than  $2\sqrt{p}$  in magnitude for any  $p$ , and the Sato-Tate conjecture (recently proven by Taylor et al) states that for a fixed elliptic curve, the  $a_p$  (suitably normalized) are asymptotically distributed in a semi-circular distribution about zero.

**Definition 1.2.** For prime  $p$ ,

- Define the *local factor*  $L_p(E, s)$  to be the function of the complex variable  $s$  as follows:

$$L_p(s) = (1 - a_p(E)p^{-s} + \epsilon(p)p^{-2s})^{-1}, \quad (1.4)$$

where  $\epsilon(p)$  is 0 if  $p$  is a *prime of bad reduction*, and 1 otherwise. [For any elliptic curve  $E$  there are only a finite number of primes of bad reduction; they are precisely the primes that divide the discriminant  $\Delta(E)$  (again, sometimes including/excluding 2 or 3)].

- The **(global)  $L$ -function**  $L(E, s)$  **attached to  $E$**  is defined to be the product of all the local  $L$ -functions, namely

$$L(E, s) = \prod_p L_p(E, s) \quad (1.5)$$

The above representation of  $L_E(s)$  is called the Euler product form of the  $L$ -function. If we multiply out the terms and use power series inversion we can also write  $L_E(s)$  as a *Dirichlet series*:

$$L(E, s) = \sum_{n=1}^{\infty} a_n(E)n^{-s}, \quad (1.6)$$

where for non-prime  $n$  the coefficients  $a_n$  are defined to be exactly the integers you get when you multiply out the Euler expansion.

If you do some analysis, using Hasse's bound on the size of the  $a_p(E)$  and their distribution according to Sato-Tate, one can show that the above two representations only converge absolutely when the real part of  $s$  is greater than  $\frac{3}{2}$ , and conditionally for  $\text{Re}(s) > \frac{1}{2}$ . However, the modularity theorem of Breuil, Conrad, Diamond, Taylor and Wiles [BCDT01] [TW95] [Wil95] states that these elliptic curve  $L$ -functions can actually be analytically continued to the entire complex plane. That is, for every elliptic curve  $L$ -function  $L(E, s)$  as defined above, there is an entire function on  $\mathbb{C}$  which agrees with the Euler product/Dirichlet series definition for  $\text{Re}(s) > 1$ , but is also defined – and explicitly computable – for all other complex values of  $s$ . This entire function is what we actually call the  $L$ -function attached to  $E$ .

The way we analytically continue  $L(E, s)$  yields that the function is highly symmetric about the line  $\text{Re}(s) = 1$ ; moreover, because the function is defined by real coefficients  $L_E(s)$  also obeys a reflection symmetry along the real axis. The point  $s = 1$  is therefore in a very real sense the *central point* for the  $L$ -function, and it is the behavior of  $L(E, s)$  at the central point that conjecturally captures the rank information of  $E$ . This is established concretely in the Birch and Swinnerton-Dyer Conjecture, the first part of which we state below (the second part is stated in the next section):

**Conjecture 1.3** (Birch, Swinnerton-Dyer, part (a)). *Let  $E$  be an elliptic curve over  $\mathbb{Q}$ , with attached  $L$ -series  $L(E, s)$ . Then the Taylor series expansion of  $L_E(s)$  about the central point  $s = 1$  is*

$$L(E, 1 + s) = s^r [C + O(s)], \quad (1.7)$$

where  $C \neq 0$ .

That is, the first part of the BSD conjecture asserts that the order of vanishing of  $L(E, s)$  at the central point is precisely the algebraic rank of  $E$ .

[Aside: Brian Birch and Peter Swinnerton-Dyer formulated the eponymous conjecture in the 1960s based in part on numerical evidence generated by the EDSAC computer at the University of Cambridge; this makes it one of the first instances of computer-generated results being used to support a mathematical hypothesis.

The BSD conjecture has now been verified for millions of elliptic curves without a single counterexample having been found; it is thus widely held to be true.]

We can therefore at least conjecturally determine the curve’s algebraic rank by computing the order of vanishing of the elliptic curve’s  $L$ -function at the central point. This converts an in general difficult algebraic problem into a perhaps more tractable numerical one.

The work in this thesis hopes to address the question of how to effectively compute the order of vanishing of  $L(E, s)$  at  $s = 1$ , which is denoted  $r_{an}$ , the *analytic rank* of  $E$ . This, again, is a non-trivial task – for example, how do you numerically determine if the  $n$ th Taylor coefficient of  $L(E, s)$  is identically zero, or just so small that it appears to be zero given precision of your numerical calculations?

The short answer is that you can’t using a finite-precision black box computer. We need theorems governing the magnitude of the Taylor coefficients – especially the leading coefficient  $C$  in the BSD conjecture – in order to make analytic rank explicitly computable. The next section more precisely lays out the problem and quotes the major results to this end derived in this work .

## 2 The $L$ -Series Leading Coefficient

**Conjecture 2.1** (Birch, Swinnerton-Dyer, part (a)). *Let  $E$  be an elliptic curve over  $\mathbb{Q}$ , with attached  $L$ -series  $L(E, s)$ . Then the Taylor series expansion of  $L_E(s)$  about the central point  $s = 1$  is*

$$L(E, 1 + s) = s^r \left[ \left( \frac{\Omega_E \cdot \text{Reg}_E \cdot \#\text{III}(E/\mathbb{Q}) \cdot \prod_p c_p}{(\#E_{\text{Tor}}(\mathbb{Q}))^2} \right) + O(s) \right], \quad (2.1)$$

where

- $r$  is the algebraic rank of  $E(\mathbb{Q})$ ,
- $\Omega_E$  is the real period of (an optimal model of)  $E$ ,
- $\text{Reg}_E$  is the regulator of  $E$ ,
- $\#\text{III}(E/\mathbb{Q})$  is the order of the Shafarevich-Tate group attached to  $E/\mathbb{Q}$ ,
- $\prod_p c_p$  is the product of the Tamagawa numbers of  $E$ , and
- $\#E_{\text{Tor}}(\mathbb{Q})$  is the number of rational torsion points on  $E$ .

For an excellent description of the conjecture and a breakdown of the arithmetic invariants mentioned above, see Andrew Wiles’ official description of the BSD Conjecture on the Clay Math website [Wil14].

## 3 Bounding the Regulator

To define the regulator of a rational elliptic curve, we must first define the naïve logarithmic height, Néron-Tate canonical height and the Néron-Tate pairing on points on  $E$ .

Let  $E$  be an elliptic curve over  $\mathbb{Q}$  and  $P \in E(\mathbb{Q})$  a rational point on  $E$ .

**Definition 3.1.** The *naïve logarithmic height* of  $P$  is a measure of the “complexity” of the coefficients of  $P$ . Specifically, any non-identity rational point  $P$  may be written as  $P = (\frac{a}{d^2}, \frac{b}{d^3})$ , with  $a, b, d \in \mathbb{Z}$ ,  $d > 0$  and  $\gcd(a, b, d) = 1$ ; we then define the naïve height of  $P$  to be

$$h(P) := \ln(d). \quad (3.1)$$

Moreover, define  $h(\mathcal{O}) = 0$ .

If you compute the naïve heights of a number of points on an elliptic curve, you’ll notice that the naïve height function is “almost a quadratic form” on  $E$ . That is  $h(nP) \sim n^2 h(P)$  for integers  $n$ , up to some constant that doesn’t depend on  $P$ . We can turn  $h$  into a true quadratic form as follows:

**Definition 3.2.** The *Néron-Tate height* height function  $\hat{h} : E(\mathbb{Q}) \rightarrow \mathbb{R}$  is defined as

$$\hat{h}(P) := \lim_{n \rightarrow \infty} \frac{h(2^n P)}{(2^n)^2}, \quad (3.2)$$

where  $h$  is the naïve logarithmic height defined above.

**Theorem 3.3** (Néron-Tate). *Néron-Tate has defines a canonical quadratic form on  $E(\mathbb{Q})$  modulo torsion. That is,*

1. For all  $P, Q \in E(\mathbb{Q})$ ,

$$\hat{h}(P + Q) + \hat{h}(P - Q) = 2 \left[ \hat{h}(P) + \hat{h}(Q) \right] \quad (3.3)$$

*i.e.  $\hat{h}$  obeys the parallelogram law;*

2. For all  $P \in E(\mathbb{Q})$  and  $n \in \mathbb{Z}$ ,

$$\hat{h}(nP) = n^2 \hat{h}(P) \quad (3.4)$$

3.  $\hat{h}$  is even, and the pairing  $\langle \cdot, \cdot \rangle : E(\mathbb{Q}) \times E(\mathbb{Q}) \rightarrow \mathbb{R}$  by

$$\langle P, Q \rangle = \hat{h}(P + Q) - \hat{h}(P) - \hat{h}(Q) \quad (3.5)$$

*is bilinear;*

4.  $\hat{h}(P) = 0$  iff  $P$  is torsion;

5. We may replace  $h$  with another height function on  $E(\mathbb{Q})$  that is “almost quadratic” without changing  $\hat{h}$ .

For a proof of this theorem and elaboration on the last point, see [Sil85, pp. 227-232].

**Definition 3.4.** The *Néron-Tate pairing* on  $E/\mathbb{Q}$  is the bilinear form  $\langle \cdot, \cdot \rangle : E(\mathbb{Q}) \times E(\mathbb{Q}) \rightarrow \mathbb{R}$  by

$$\langle P, Q \rangle = \hat{h}(P + Q) - \hat{h}(P) - \hat{h}(Q) \quad (3.6)$$

Note that this definition may be extended to all pairs of points over  $\overline{\mathbb{Q}}$ , but the definition above suffices for our purposes.

If  $E(\mathbb{Q})$  has rank  $r$ , then  $E(\mathbb{Q})/E_{\text{tor}}(\mathbb{Q}) \hookrightarrow \mathbb{R}^r$  under the quadratic form  $\hat{h}$  as a (rank  $r$ ) lattice.

**Definition 3.5.** The *regulator*  $\text{Reg}_E$  of  $E/\mathbb{Q}$  is the covolume of the lattice that is the image of  $E(\mathbb{Q})$  under  $\hat{h}$ . That is, if  $\{P_1, \dots, P_r\}$  generates  $E(\mathbb{Q})$ , then

$$\text{Reg}_E = \det (\langle P_i, P_j \rangle)_{1 \leq i, j \leq r} \quad (3.7)$$

where  $(\langle P_i, P_j \rangle)_{1 \leq i, j \leq r}$  is the matrix whose  $(i, j)$ th entry is the value of the pairing  $\langle P_i, P_j \rangle$ . If  $E/\mathbb{Q}$  has rank zero, then  $\text{Reg}_E$  is defined to be 1.

Note that if  $E/\mathbb{Q}$  has rank 1, then its regulator is just the smallest height of a non-torsion point  $P \in E(\mathbb{Q})$ .

Loosely, the regulator measures the “density” of rational points on  $E$ : positive rank elliptic curves with small regulators have many points with small coordinates, while those with large regulators have few such points.

It turns out that one can construct elliptic curves with arbitrarily large regulators (for example, fix some  $x_0$  and  $y_0$  with large denominators, and then find  $A$  and  $B$  such that  $P = (x, y)$  lies on  $E : y^2 = x^2 + Ax + B$ ). However, the more interesting question to ask – and the one that is relevant to this thesis – is “how small can the regulator get?”. Specifically, given  $E/\mathbb{Q}$  with discriminant  $D_E$ , what is the smallest  $\text{Reg}_E$  can be as a function of  $D_E$ ?

This is an open question. However, the following conjecture has been made by Lang [Lan97]:

**Conjecture 3.6.** *Let  $E/\mathbb{Q}$  have minimal discriminant  $\Delta_E$ . There exists an absolute constant  $M_0 > 0$  independent of  $E$  such that any non-torsion point  $P \in E(\mathbb{Q})$  satisfies*

$$\hat{h}(P) \geq M_0 \log |\Delta_E|. \quad (3.8)$$

That is, the minimum height of a non-torsion point on  $E$  scales with the log of the absolute value of the curve's minimal discriminant. Hindry and Silverman in [HS88] show that the abc conjecture implies Lang's height conjecture; since we are already assuming strong abc, we have this result for free.

Since the conductor of a curve always divides the minimal discriminant, an immediate consequence of the height conjecture is the following:

**Corollary 3.7.** *Let  $E/\mathbb{Q}$  have conductor  $N_E$ . There exists an absolute constant  $M_1 > 0$  independent of  $E$  such that any non-torsion point  $P \in E(\mathbb{Q})$  satisfies*

$$\hat{h}(P) \geq M_1 \log N_E. \quad (3.9)$$

(Note that the two versions of the height conjecture are fully equivalent under Szpiro's Conjecture).

**Conjecture 3.8.**  $M_0 = 0.000213016731929803\dots$  and  $M_1 = 0.00107510998642534\dots$ ; these two constants are attained by the rank 1 curve  $E : y^2 + xy + y = x^3 + x^2 - 125615x + 61201397$  with Cremona label 3990v1, conductor  $N_E = 3990$  and minimal discriminant  $\Delta_E = -1494018600480000000$ . Furthermore, the curve's generator for the group of rational points  $P = (7107, -602054)$  and its negative attain the minimum height of any non-torsion point on any elliptic curve over  $\mathbb{Q}$ , namely  $\hat{h}(P) = 0.00891432445568635\dots$

This conjecture is grounded on numerical evidence.

This allows us to bound the regulator of  $E$  from below in terms of its conductor and the global constant  $M_1$ :

**Theorem 3.9.** *Let  $E/\mathbb{Q}$  have conductor  $N_E$ . Assume strong abc, and let  $M_1$  be the absolute constant in Lang's height conjecture. Then*

$$\text{Reg}_E \geq \text{What goes here?} \quad (3.10)$$

*Proof.* Let  $E$  have minimal discriminant  $\Delta_E$  and algebraic rank  $r$ . Since  $|\Delta_E| \geq N_E$ , it follows that

$$\text{Reg}_E \geq (M_1 \log N_E)^r \geq M_1^r$$

Numerically we determine that  $M_1 < 1$ . For example, the rank 1 curve with Cremona label 1430k1 has a group generator with height 0.009739...; its regulator is therefore the same value. We thus must have that  $M_1 \leq 0.00974 / \log(1430) = 0.001340\dots$

From Lemma ??? we have that  $r < \frac{1}{5} \log N$ ; hence

□
